(Dated: October 27, 2019)

Although gravitational waves (GWs) only interact weakly with matter, their propagation is affected by a gravitational potential. If a GW source is eclipsed by a star, measuring these perturbations provides a way to directly measure the distribution of mass throughout the stellar interior. We compute the expected Shapiro time delay, amplification and deflection during an eclipse, and show how this can be used to infer the mass distribution of the eclipsing body. We identify continuous GWs from neutron stars as the best candidates to detect this effect. When the Sun eclipses a far-away source, depending on the depth of the eclipse the time-delay can change by up to ~ 0.035 ms, the GW strain amplitude can increase by $\sim 4\%$ and the apparent position of the source in the sky can vary by $4''$. Accreting neutron stars with Roche-lobe filling companion stars have a high probability of exhibiting eclipses, producing similar time delays but undetectable changes in amplitude and sky location. Even for the most rapidly rotating neutron stars, this time delay only corresponds to a few percent of the phase of the GW, making it an extremely challenging measurement. However, if sources of continuous GWs exist just below the limit of detection of current observatories, next-generation instruments will be able to observe them with enough precision to measure the signal of an eclipsing star. Detecting this effect would provide a new direct probe to the interior of stars, complementing asteroseismology and the detection of solar neutrinos.

I. INTRODUCTION

The subject of lensing of gravitational waves (GWs) was studied in the early 1970s and 1980s in the context of amplifying possible signals to the point of detection. This was in part driven by claims of the observation of GWs using cylindrical bar detectors [1], for which the reported amplitude was too high to be explained by astrophysical sources. Considering the Galactic core as a lens, it was shown that this was insufficient to explain those detections [2, 3]. Lensing by the Sun was also shown to be unimportant for the observation of GWs, as diffraction effects imply that a significant amplification of the signal is only expected for GWs with frequencies $> 10^4$ Hz [3–5]. This is higher than the frequencies of known astrophysical GW sources, which are not expected to exceed a few kilohertz [6]. Currently, strong lensing is only expected to affect a small number of observable sources of GWs [7–9], and there is no strong evidence for current detections having been strongly lensed [10]. Microlensing of GWs is also considered to be an unlikely event, but owing to the relatively low frequencies of GW sources can lead to wave-optical phenomena that allow the inference of additional information about the lens [11, 12].

Even if GW lensing is not expected to play a role in the

majority of observable sources, measuring small effects of intervening matter on GWs can provide interesting astrophysical information. The detection of GWs from merging binary black holes (BHs [13, 14]) and neutron stars (NSs [14, 15]) by the Advanced LIGO [16] and Virgo [17] detectors makes it possible to use them as astrophysical tools. In particular, GWs crossing the interior of a star carry information on its internal mass distribution. For instance, it has been proposed that measuring the deflection angle of a GW source eclipsed by the Sun will yield the Solar density profile [18].

In this paper we discuss the effects of eclipsing stars on high-frequency GWs detected at Earth, and how these provide information on the interior of the eclipsing star. In Section II we discuss different sources of GWs that could be used for this purpose, and show that high-frequency continuous GWs (CWs) work best. In Section III we analyze the effects produced on high-frequency GWs crossing the interior of the Sun using both geometric and wave optics, while in Section IV we discuss the case where the eclipsing star is a binary companion to the source of GWs. We explore the detectability of these effects in Section V, and give our conclusions in Section VI. All code used to produce figures and compute our results is available at [19].

FIG. 1. Probability of observing at least one eclipsing source as a function of the number of observed sources. Colors indicate different types of sources, while line styles indicate the depth of the eclipse. For the case of CBCs and CWs eclipsed by the Sun, probabilities are computed assuming an isotropic distribution in the sky, and an observer on Earth. Probabilities for the case of an accreting NS being eclipsed by its companion are computed assuming a mass ratio $q \equiv M_{\text{NS}}/M_2 = 10$ and by approximating the stellar companion as a sphere with a radius equal to its Roche lobe.

II. CONTINUOUS GWS OR COMPACT BINARY COALESCENCES

Although only GWs from compact binary coalescences (CBCs) have been directly detected to date [14], these sources are not useful for extracting information from an eclipsing event. If we are interested in observing a source behind the Sun, the probability of observing this for a CBC (assuming they are isotropically distributed) is given by the fraction of the sky that is covered by the Solar disk which has an angular diameter of $\sim 32'$. This is because such sources pass quickly through the ground-based detector band, and during this time the position of the Sun is essentially static. The probability of it being located behind the Sun is then just 0.00054%, and even after 10^4 observations, there's only a 5.3% chance that at least one source is eclipsed. Even if an eclipsing CBC is detected to high precision, it is difficult to distinguish effects inherent to the source from those produced by the eclipsing star in the absence of previous information about the source. GW signals from a CBC source are short-lived in the LIGO-Virgo band (a binary neutron star evolves from a GW frequency of 10 Hz to merger in less than 20 minutes) relative to the duration of an eclipse; this makes it implausible to compare the signal of an eclipsed source against its pre- or post- eclipse signal.

On the other hand, CWs are ideal for this purpose as

any source located $\lesssim 16'$ from the ecliptic and lasting more than a year will be eclipsed by the Sun. The probability of a single source undergoing an annual eclipse (assuming an isotropic distribution) is 0.47%, and with 200 sources the probability that at least one will undergo an eclipse is 61% (see Fig. 1). The likelihood of this happening is actually larger; unlike CBCs, many expected sources of CWs are Galactic and thus not isotropically distributed in the sky, and the Sun crosses the Galactic bulge. Moreover, a CW can be studied and characterized *before* a lensing event, making it easier to extract information from an eclipse.

In terms of expected sources of CWs, binary white dwarfs will be a prime source for the LISA observatory [20], with known sources predicted to be detectable given the design sensitivity of the instrument [21, 22]. However, the wavelengths of these sources are larger than the Sun, as are the arms of the LISA constellation itself. Any effects produced by the Sun on such long-wavelength sources are small due to diffraction. As we show later, signals with GW frequencies below 10 Hz are essentially unperturbed by the Sun.

Rotating NSs are potential sources of high frequency CWs [23, 24]; a NS with a non-zero quadrupolar moment is expected to emit GWs at a frequency $f_{\text{GW}} = 2\nu$, where ν is the rotational frequency of the NS [25]. For known pulsars with measured time derivatives, a rough upper limit on the strength of emitted GWs can be obtained by assuming its spin-down is solely due to energy emitted in GWs. The latest searches for isolated sources using data from the first and second observing runs of Advanced LIGO, have not resulted in a detection [26–28]. However, the searches made for known pulsars [26, 27] have further increased the sample of young pulsars for which the spin-down limit is reached to 20, and are within factors of a few of the spin-down limit for some millisecond pulsars (MSPs).

Accreting millisecond X-ray pulsars (AMXPs) with a Roche-lobe filling companion are expected to be particularly strong sources of high-frequency CWs. These objects are believed to reach a point where accretion spin-up is compensated by energy losses from the emission of GWs [29, 30], which could also result from the excitation of the r-mode instability [31]. Moreover, systems undergoing Roche lobe overflow have a high probability that the compact object is eclipsed by its companion (see Fig. 2 and Fig. 1). For a system with a mass ratio $q \equiv M_{\text{NS}}/M_2 = 10$, the probability that it undergoes eclipses is $\sim 20\%$, and in particular there is one known eclipsing AMXP, SWIFT J1749.4–2807 [32].

As depicted in Fig. 2, there are two different situations of interest. If GWs cross the Sun, then measuring them we could extract information about the Solar interior. Meanwhile, if the eclipsing source is the companion star of an accreting MSP, GWs provide a probe into the mass distribution of the companion. Eclipses by the Sun would happen annually and last at most 12 hours, while eclipses from the companion of an accreting source would happen

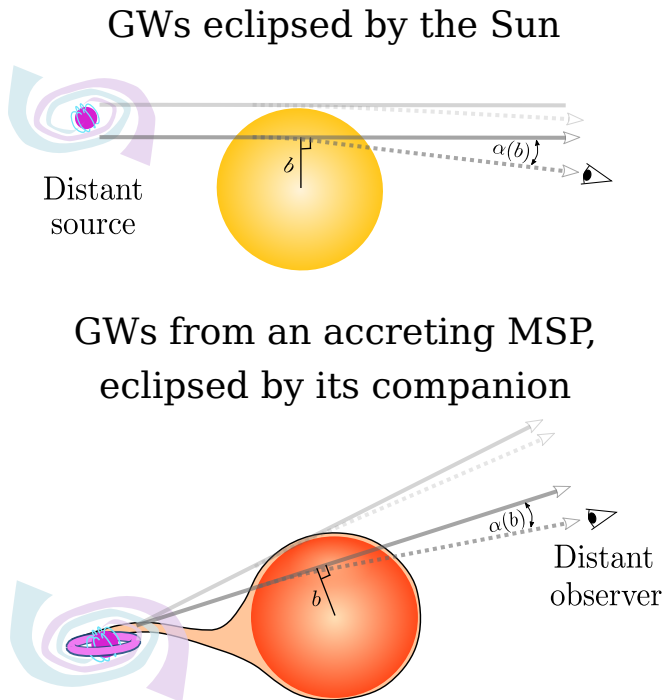

FIG. 2. Two different types of eclipses that could allow the measurement of the internal mass distribution of stars. (top) Eclipse of a distant GW source by the Sun, observed at Earth. In this case, all rays approaching the Sun are essentially parallel to each other, resulting in caustics far from Earth. (bottom) GWs from an accreting NS eclipsed by its companion.

every orbit, and could last for more than 10% of the orbital period depending in the orbital inclination and the mass ratio.

In Table I we summarize a few known sources of interest. From the ATNF pulsar catalogue [39] we find two recycled millisecond pulsars (MSPs) that are eclipsed by the Sun, J1022+1001 and J1730–2304. MSPs are stable clocks (cf. [40]), such that timing of GWs and measurement of the Shapiro delay [41] during an eclipse might be possible. MSPs have low spin-down limits, and Advanced LIGO and Virgo at design sensitivity are not guaranteed to detect either of these sources [26]. In contrast, the spin-down limit has been reached for the Crab pulsar [42], but it is not eclipsed by the Sun. Young pulsars also exhibit sudden frequency shifts called glitches [43] which make timing of the signal difficult for extended periods of time. But even for prolific glitchers like the Crab there have not been two glitches detected less than 10 days apart from each other [35], making the likelihood of a glitch happening during an eclipse small. Six more pulsars from the ATNF catalogue are eclipsed by the Sun, but their low frequencies ($\nu < 10$ Hz) make

them unsuitable.

Sco X-1 and XTE J1751–305 are two AMXPs which are close to the ecliptic, though not close enough to be eclipsed by the Sun. Searches of the first and second observing runs of Advanced LIGO have provided upper limits on potential GW emission from Sco X-1 [44–46], and searches of initial LIGO data have provided upper limits for XTE J1751–305 [47]. SWIFT J1749.4–2807 is also an AMXP, and a particularly interesting source because it undergoes periodic eclipses from its companion. The number of AMXPs has grown significantly in the last decade [48]. Although none of the 19 AMXPs known so far are eclipsed by the Sun, it is likely that an eclipsing source will be found with further detections. This is particularly relevant, as AMXPs are a favoured candidate for the first detection of high-frequency GWs [49].

III. EFFECTS OF THE SUN ON ECLIPSED GWS

We consider the impact of three different effects. As a GW signal passes near the Sun, it experiences gravitational deflection, which also impacts the apparent luminosity of the source. In addition, the time of arrival of signals is delayed compared to what would happen if the Sun was absent, which constitutes the Shapiro delay [41]. We first use geometrical optics to compute these effects as observed from the Earth, and then perform wave optics calculations to check at which frequencies geometric optics is a good approximation. We use a Solar model computed with the MESA [50–53] code, and all calculations assume a radial distribution for the mass of the Sun. The Earth is located far from the caustics produced by the Solar lens, and in its neighborhood the predicted perturbations to the waveform vary on lengthscales of the order of R_\odot . We then expect the geometric optics approximation to apply for $\lambda \ll R_\odot$, which is the case for rapidly rotating NSs that emit GWs at frequencies above 1000 Hz.

A. Deflection and amplification

The deflection and amplification produced by a spherically symmetric gravitational lens are well known results of lensing theory (cf. [54]). The deflection angle can be obtained in terms of the distance of closest approach b , and the mass contained within an infinite cylinder of radius b centered at the lens, $M_{\text{cyl}}(b)$. For the Sun, the deflection angle is

$$\alpha(b) = \frac{4GM_{\text{cyl}}(b)}{c^2b} = 1.75'' \frac{M_{\text{cyl}}(b)}{M_\odot} \left(\frac{b}{R_\odot} \right)^{-1}. \quad (1)$$

Figure 3 shows the expected effect from a detailed Solar model, showing that the maximum angle of deflection is smaller than $5''$. An observer does not measure this

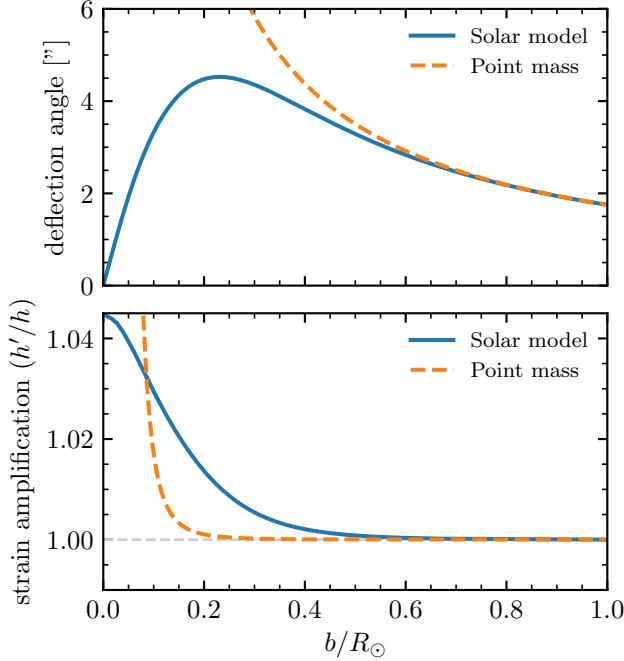

FIG. 3. (top) Deflection α of a GW as a function of its distance of closest approach to the center of the Sun. (bottom) Amplification of the GW strain as a function of its distance of closest approach to the center of the Sun, considering a detector located at the Earth. In both panels, the dashed line indicates the corresponding effect if the Sun were a point mass.

angle directly, but instead detects an angular variation $\Delta\theta$ for the location of the source in the sky. Defining the optical axis as the line joining the center of the lens and the source, and the optical plane as the plane perpendicular to the optical axis that crosses the lens, we approximate the effect of the lens as simply kinking an incoming ray by an angle $\alpha(b)$ at the optical plane (see Fig. 4). In addition, b is approximated as the distance of closest approach of the undeflected ray. This is a standard approximation that is justified when the deflection angle α is small [55]. Under these assumptions we have

FIG. 4. Definition of variables used to compute the change in sky location and amplification of signals from the Solar lens. The deflection angle is greatly exaggerated.

that

$$\Delta\theta = \alpha \sqrt{\frac{d_{ls}^2 + b'^2}{l^2 + (d_{ls} + d_l)^2}}, \quad (2)$$

where we have assumed $\Delta\theta$ and α are small angles, d_{ls} is the distance between the source and the lens and d_l is the distance between the source and the observer along the optical axis. The distance between the center of the lens and the point where the undeflected ray would intersect the optical plane is denoted by b' , while the distance between the observer and the optical axis is denoted as l . The values of b' and l can be computed as

$$b' = \frac{bd_{ls}}{\sqrt{d_{ls}^2 - b^2}}, \quad l = \frac{d_{ls} + d_l}{d_{ls}} b' - d_l \alpha(b). \quad (3)$$

Considering a distant source lensed by the Sun and observed from Earth, $d_{ls} \gg d_l$ and $d_{ls} \gg l$, such that Eq. (2) results in $\Delta\theta \simeq \alpha$ (i.e. the deflection angle is equal to the apparent change in location of the source). Measuring this deflection angle would provide a direct measurement of the Solar mass distribution [18].

The change in strain is equal to the square root of the change in luminosity. Following Fig. 4 and applying the geometrical optics approximation results in [54]

$$\frac{h'(b)}{h} = \left(\frac{d_{ls} + d_l}{d_{ls}} \right) \sqrt{\frac{b'}{l}} \left(\frac{d_{ls} + d_l}{d_{ls}} - d_l \frac{d\alpha}{db} \right)^{-1/2}, \quad (4)$$

where h is the strain that would be measured in the absence of lensing. For the case of a distant source being

lensed by the Sun $d_{ls} \gg d_l$ and b' is almost equal to b , leading to

$$\frac{h'(b)}{h} = \left(\frac{b}{b - a_{\oplus} \alpha(b)} \right)^{1/2} \left(1 - a_{\oplus} \frac{d\alpha}{db} \right)^{-1/2}, \quad (5)$$

where $d_l = a_{\oplus} = 1$ au. The result from our Solar model is shown in Fig. 3. The maximum amplification happens at the core of the Sun, and is just a factor 1.045 of the non-lensed strain. In contrast, a point mass results in no amplification during most of an eclipse, with a steep rise below $b/R_{\odot} \sim 0.1$. The large deflection angles that would be produced by a point mass result in rays with $b/R_{\odot} \sim 0.05$ focusing at 1 au from the Sun, at which point the geometric optics approximation is not valid.

B. Shapiro delay

The time delay of a signal as it passes by the Sun, compared to the arrival time the signal would have in the absence of the Sun, is given by [41, 56]

$$\Delta t = -\frac{2}{c^3} \int_A^B \Phi dl, \quad (6)$$

where A and B denote the location of the source and the receiver, and Φ is the gravitational potential of the Sun which satisfies Poisson's equation $\nabla^2 \Phi = 4\pi G\rho$ and, assuming spherical symmetry for the Sun, is given by $\Phi = -GM_{\odot}/r$ for $r > R_{\odot}$. Equation (6) is given in coordinate time, and the actual time delay measured on Earth includes additional small corrections that depend on the Solar System ephemerides [56]. The integral in Eq. (6) can be estimated by integrating through the straight line path that the unperturbed light ray would follow, as the additional delay produced by the deflection of the null geodesic only adds up to a few tens of nanoseconds [57]. If the trajectory does not go through the Sun, then Eq. (6) is equal to

$$\Delta t_{\text{out}} = -\frac{2GM_{\odot}}{c^3} \ln \left(\frac{\hat{n} \cdot \vec{a}_{\oplus} + a_{\oplus}}{\hat{n} \cdot \vec{a}_s + a_s} \right), \quad (7)$$

where \vec{a}_s and \vec{a}_{\oplus} are the positions of the source and the receiver with respect to the Sun, and \hat{n} is a unit vector from the receiver to the source. If the source is far away, such that $\hat{n} \cdot \vec{a}_s + a_s \simeq 2a_s$, the time delay can be approximated as

$$\Delta t_{\text{out}} = -\frac{2GM_{\odot}}{c^3} \ln \left[\frac{a_{\oplus}}{2a_s} (1 - \cos \beta) \right], \quad (8)$$

where β is the angle in the sky between the center of the Sun and the source ($\cos \beta = -\hat{n} \cdot \vec{a}_{\oplus}/a_{\oplus}$). For sources close to the Solar disk β is small, such that the time delay can be expressed in terms of the distance of closest approach to the Sun $b \simeq \beta a_{\oplus}$,

$$\Delta t_{\text{out}} = -\frac{4GM_{\odot}}{c^3} \ln \left(\frac{b}{2\sqrt{a_{\oplus} a_s}} \right). \quad (9)$$

If the line does go through the Sun, then this equation has to be corrected for the part of the trajectory that crosses it,

$$\Delta t = \Delta t_{\text{out}} - \Delta t_{-} + \Delta t_{+}, \quad (10)$$

$$\Delta t_{-} = \frac{2}{c^3} \int_{A'}^{B'} \frac{GM_{\odot}}{r} dl, \quad (11)$$

$$\Delta t_{+} = \frac{2}{c^3} \int_{A'}^{B'} \Phi(r) dl, \quad (12)$$

where A' and B' are the points where the trajectory crosses the surface of the Sun. Computing Δt_{-} yields

$$\Delta t_{-} = -\frac{4GM_{\odot}}{c^3} \ln \left(\frac{b}{R_{\odot} + \sqrt{R_{\odot}^2 - b^2}} \right), \quad (13)$$

while Δt_{+} can be transformed into an integral over the mass coordinate of the Sun,

$$\begin{aligned} \Delta t_{+} &= -\frac{4}{c^3} \int_b^{R_{\odot}} \frac{\Phi(r)r}{\sqrt{r^2 - b^2}} dr \\ &= \frac{4GM_{\odot}}{c^3} \frac{\sqrt{R_{\odot}^2 - b^2}}{R_{\odot}} \\ &\quad + \frac{4}{c^3} \int_b^{R_{\odot}} \frac{Gm(r)}{r^2} \sqrt{r^2 - b^2} dr, \end{aligned} \quad (14)$$

where we have used $d\Phi/dr = Gm(r)/r^2$ and $\Phi(R_{\odot}) = -GM_{\odot}/R_{\odot}$. Since only relative changes in the arrival time of pulses can be determined, it is more useful to consider the difference between the delay time for b , and the delay time of a signal that passes right by the surface of the Sun ($b = R_{\odot}$). Combining Eq. (9), (12), (13) and (14) then gives us the time delay as a function of b and the mass profile of the Sun $m(r)$,

$$\begin{aligned} \Delta t(b) - \Delta t(R_{\odot}) &= -\frac{4GM_{\odot}}{c^3} \\ &\times \left[\ln \left(\frac{R_{\odot} + \sqrt{R_{\odot}^2 - b^2}}{R_{\odot}} \right) - \frac{\sqrt{R_{\odot}^2 - b^2}}{R_{\odot}} \right. \\ &\quad \left. - \frac{1}{M_{\odot}} \int_b^{R_{\odot}} \frac{m(r)}{r^2} \sqrt{r^2 - b^2} dr \right]. \end{aligned} \quad (15)$$

This can be rewritten in a way that clearly distinguishes the contribution for the case of a point mass,

$$\begin{aligned} \Delta t(b) - \Delta t(R_{\odot}) &= -\frac{4GM_{\odot}}{c^3} \left[\ln \left(\frac{b}{R_{\odot}} \right) \right. \\ &\quad \left. - \frac{1}{M_{\odot}} \int_b^{R_{\odot}} \frac{M_{\odot} - m(r)}{r^2} \sqrt{r^2 - b^2} dr \right] \end{aligned} \quad (16)$$

The factor $4GM_{\odot}/c^3 = 0.02$ ms shows how small the expected effect is. The time delay is plotted in Fig. 5, and the largest delay is of ~ 0.035 ms for a source crossing the center of the Sun. This represents a shift in the phase

FIG. 5. The time delay imprinted on a GW as a function of its distance of closest approach to the center of the Sun. The solid line shows the delay derived from a detailed Solar model computed with the *MESA* code, while the dashed line is the effect from a point mass and represents an absolute upper limit. The two dotted vertical lines indicate the lowest value of b reached by the two known MSPs that are eclipsed by the Sun.

of the pulsars listed in Table I ranging from a half of a percent to a few percent. When the source is not eclipsed the Shapiro delay still changes depending on the angle β between the locations of the source and the Sun in the sky. Combining Eq. (8) and Eq. (9) and considering a source antialigned with the Sun ($\beta = \pi$) results in

$$\Delta t(\beta = \pi) - \Delta t(R_\odot) = -\frac{4GM_\odot}{c^3} \ln\left(\frac{2a_\oplus}{R_\odot}\right) \quad (17)$$

$$= -0.12 \text{ ms.}$$

The magnitude of this orbital variation in the time delay is larger than that during an eclipse, but it can only provide information on the total mass of the Sun rather than its internal structure.

Equation (16) provides information on the Solar interior in the form of an integral over the mass distribution. If the derivative of the time delay as a function of b can be measured as the source passes behind the Sun, it provides a direct measurement of $M_{\text{cyl}}(b)$,

$$\frac{d\Delta t}{db} = -\frac{4GM_{\text{cyl}}(b)}{c^3 b} = -\frac{\alpha(b)}{c}. \quad (18)$$

This relation between the deflection angle and the time delay is exactly what is expected in terms of the change in direction of propagation of an incoming wavefront.

C. Wave optics

Calculations using geometric optics are only valid in the limit that the effects of the lens on the amplitude,

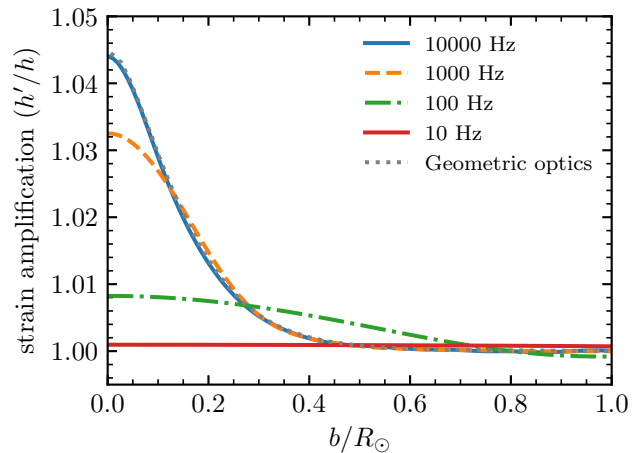

FIG. 6. Amplification of the GW strain observable at Earth during an eclipse. Each line indicates a different frequency, while the geometric optics result is the expected value in the limit that $f_{\text{GW}} \rightarrow \infty$.

phase, and direction of propagation of a wave occur on lengthscales much larger than a wavelength, and on timescales much longer than the period of the wave. For the case of an eclipse by the Sun being observed at Earth, all predicted effects on incoming waves are small and operate on a lengthscale $\sim R_\odot$, such that the geometric optics approximation requires $\lambda \ll R_\odot$. The timescale on which the properties of the wave change corresponds to the length of the eclipse τ_{ec} , which sets a limit on the frequency of the source for the applicability of geometric optics, $f_{\text{GW}}^{-1} \ll \tau_{\text{ec}}$. The tighter constraint is provided by the limit on the wavelength; for $\lambda = R_\odot$ the corresponding frequency is $f_{\text{GW}} \sim 0.5$ Hz, so the geometric optics approximation requires $f_{\text{GW}} \gg 0.5$ Hz. Because of this, we only expect the predicted effects to be of relevance for high frequency GWs observable by ground based observatories, while at lower frequencies GWs would be unaffected by the lens.

For practical purposes, it is necessary to quantify how much smaller than R_\odot the wavelength needs to be for the effects of the Solar lens to become important. For this, we need to drop the assumption of geometric optics. Following [4, 58] we compute the Kirchhoff integral, which allows the calculation of a wave given its properties on a surface surrounding the observation point. The effect of the lens is encoded by the time delay given by Eq. (16), which produces a phase shift at the lens plane. Given this, the Kirchhoff integral can be numerically computed to determine the amplification and the time delay observable at any point in space (see Appendix A).

Using our Solar model, we compute the amplitude and time delays observable at Earth through an eclipse for sources at different frequencies, which we show together with the expected results from geometric optics in Fig. 6 and 7. As expected, at frequencies below 10 Hz the am-

FIG. 7. Time delay observable at Earth during an eclipse. Each line indicates a different GW frequency; the geometric optics result is the expected value in the limit that $f_{\text{GW}} \rightarrow \infty$.

plication and the time delay are negligible, meaning that waves with that frequency are unaffected by the Solar lens. At 100 Hz the magnitude of the amplification and time delay is on the same order of magnitude as those predicted by geometric optics, but there are significant discrepancies produced by wave optics. At 10^3 Hz, the effects predicted using wave optics closely match those of geometric optics except for the inner 10% of the Sun, with the amplification and time delays for a source passing through the very center of the Sun being $\sim 30\%$ and 5% lower than the results of geometric optics. At 10^4 Hz, the predicted effects become almost equivalent to those of geometric optics.

These results show that the ideal sources to extract information about the Solar interior are GWs with $f_{\text{GW}} \geq 10^3$ Hz, as at these frequencies the amplitude of the predicted effects is almost maximal, and having results close to the geometric optics prediction makes the inverse problem of deducing the structure of the Sun from the signal easier. This has to be put in contrast with the results of [3, 4, 58], who determined that no significant amplification can happen for waves with frequencies $f_{\text{GW}} < 10^4$ Hz. The main difference with our work is that they were considering amplification at the caustics of the Sun, regions in space where multiple images are formed and geometric optics predicts infinite amplification. The situation we are studying is significantly different, as the Earth is located far away from a caustic. From our computed Solar model, the nearest caustics to the Sun are at a distance of ~ 20 au from it, near the orbit of Uranus. So in contrast to that previous work, at the Earth we find that the geometric optics limit is fully recovered for sources at 10^4 Hz.

Despite our expectation that CBCs occurring behind the Sun are extremely uncommon, if one happens right behind the center of the Sun it would experience an

anomalous increase in amplitude of a few percent. This is because as the source chirps to higher frequencies, the predicted amplitude will approach the expected result from geometric optics.

IV. GWS IN ACCRETING NEUTRON STARS ECLIPSED BY A BINARY COMPANION

When the eclipse is produced by a nearby binary companion of the GW source we have that the orbital separation $a = d_{ls} \ll d_l$ (see Fig. 4) and Eq. (4) yields

$$\frac{h'(b)}{h} = \left(\frac{b'}{b' - a\alpha(b)} \right)^{1/2} \left(1 - a \frac{d\alpha}{db} \right)^{-1/2}. \quad (19)$$

This is equivalent to Eq. (5) for sources eclipsed by the Sun, except that the distance between the Earth and the Sun a_{\oplus} is replaced by the orbital separation a , and b is switched for b' as the approximation $b \simeq b'$ is no longer valid. If we consider the eclipsing object to be a Roche-lobe filling star similar to the Sun, then $a \sim R_{\odot} \ll a_{\oplus}$, resulting in a much smaller amplification than when distant sources observed from the Earth are eclipsed by the Sun. The angle of deflection α in this case is computed in the same way as for a source eclipsed by the Sun, but the apparent change in location $\Delta\theta$ is much smaller; in the limit $d_l \gg d_{ls}$ Eq. (2) results in

$$\Delta\theta = \frac{d_{ls}}{d_l} \alpha. \quad (20)$$

Thus, we do not expect amplification or deflection to be relevant when these sources are observed using GW detectors.

However, the magnitude of the Shapiro delay that would be measurable at the Earth is the same if one considers an eclipsing Sun-like companion star as for the case of eclipsing by the Sun. The derivation is completely analogous to the one in the previous section, except that the position of the detector and the GW source are inverted. For the case of an edge-on system, Eq. (8) is also valid, with β corresponding to the angle in the sky between Earth and the binary companion, as observed from the GW source. The orbital phase is then equal to $\beta/2\pi$, and during an eclipse the small angle approximation $b = \beta a$ is still valid, where a is the orbital separation.

To evaluate the magnitude of this time delay during a mass transfer phase we use the MESA code to model a low-mass X-ray binary consisting of a $1.4M_{\odot}$ NS and a $1M_{\odot}$ zero-age main sequence stellar companion with an initial orbital period of 2 days. We account for magnetic braking as in [59], which efficiently removes orbital angular momentum from the system. This leads to Roche lobe overflow when the system is ~ 6 Gyr old and the orbital period is 0.4 days, at which point the star is similar to our Sun. Further loss of orbital angular momentum due to magnetic braking keeps shrinking the orbit and reduces the orbital period to 1.4 hr, while the mass of

the donor star decreases to $0.1M_{\odot}$ through mass transfer in ~ 2.5 Gyr.

Figure 8 shows the expected Shapiro time delay as a function of the orbital phase, in case this system is observed edge-on. Eclipses last for more than 10% of the orbital period at the beginning of mass transfer, and the expected time delay is the same as the one we computed for the Sun in the previous section. As mass transfer proceeds, the magnitude of the time delay decreases from a few tens of microseconds down to just 2 microseconds, and the duration of the eclipses decrease as well. During mass transfer the amplification of the strain is always below 0.07%, which is almost two orders of magnitude smaller than for sources eclipsed by the Sun and observed from Earth.

A GW measurement of the Shapiro time delay from the eclipsing companion will also provide an independent estimate on the properties of the system even if the resolution is insufficient to probe the companion's internal mass distribution. Coupled with the known inclination – which is constrained to be near edge-on by virtue of observing the eclipse altogether – and a measurement of the radial velocity variation of the GW source, the Shapiro time delay breaks the usual mass function degeneracy in X-ray binaries, allowing the NS mass to be inferred. For this purpose the change in the Shapiro delay through an entire orbital phase can be used. Similarly to Eq. (17), for an edge-on system observed at the point where the GW source is in front of the star, the relative delay compared to the point where $b = R$ is

$$\Delta t(\beta = \pi) - \Delta t(R_{\odot}) = -\frac{4GM}{c^3} \ln\left(\frac{2a}{R}\right), \quad (21)$$

where M and R are the mass and radius of the eclipsing star, respectively. For a Roche-lobe filling star identical to the Sun with a $1.4M_{\odot}$ companion, the orbital separation is $a = 2.9R$, and Eq. (21) gives a relative time delay of -0.034 ms, essentially doubling the effect observable just during an eclipse. However, for AMXPs X-ray timing may provide a better tool to measure the Shapiro delay (cf. [32]). Moreover, if radial velocity measurements of the companion star are available along with NS radial velocity measurements and a known inclination from eclipses, the masses can be inferred directly.

A. Number of eclipsed accreting neutron star binaries

We estimate the number of rapidly rotating NSs that are eclipsed either by a binary companion or the Sun through a population synthesis of NS binaries using the binary population synthesis code COSMIC [60]. COSMIC evolves binary systems with a modified version of the binary evolution code BSE [61]. The modified version includes updates to account for metallicity dependent winds [62, 63], neutrino driven core collapse supernova explosions [64], and compact object natal kicks [65]. We

FIG. 8. Time delay as a function of orbital phase for a system consisting of a Roche-lobe-overflowing donor star eclipsing a $1.4M_{\odot}$ NS companion. The donor is initially a $1M_{\odot}$ star at Solar metallicity in a binary with an initial orbital period of 2 days. Each solid line corresponds to a different point in time as mass transfer reduces the mass of the donor star to the value appearing in the caption, and shows the expected time delay from geometric optics for an edge-on system. Dotted lines indicate the expected time delay for the case of a point mass rather than a donor star model with an extended mass distribution.

TABLE II. Star formation history (SFH) for Galactic components following [67].

Component	Age [Gyr]	SFH	$Z [Z_{\odot}]$	Mass [M_{\odot}]
Thin Disk	10	constant	1	4.32×10^{10}
Thick Disk	11	1 Gyr burst	0.15	1.44×10^{10}
Bulge	10	1 Gyr burst	1	8.9×10^9

treat the star formation history (SFH) for the Milky Way Thin Disk, Thick Disk, and Bulge populations separately as outlined in Table II. All binaries are initialized according to the observationally derived correlated joint probability distribution of [66] over the primary mass, secondary mass, orbital period, eccentricity, and multiplicity of each binary. We assume all systems with a multiplicity greater than one are binary systems, thus ignoring triples and higher multiplicity systems.

We simulate all binaries from the zero-age main sequence and restrict our attention to the population containing a NS that is accreting from a stellar donor with $M_D > 0.05 M_{\odot}$ at present. This criterion removes NSs that would experience time delays on the order of a microsecond or less when eclipsed by their companions; black widow pulsars, which are observed to eclipse, fall into this category [68–72] and so produce sub-microsecond time delays. We iteratively simulate binary populations until the mass and orbital period distributions converge.

We generate 500 simulated Milky Way populations

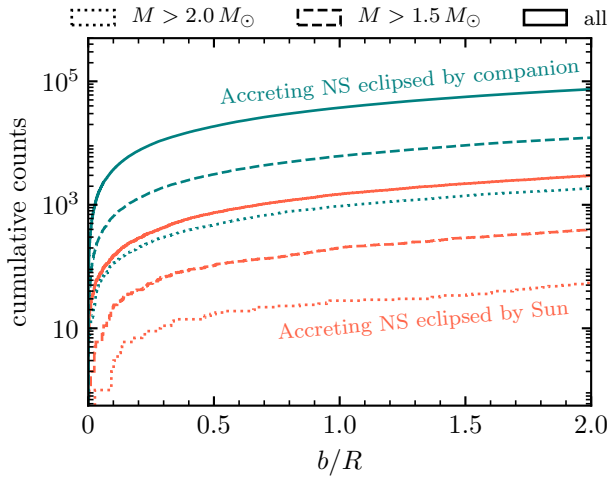

FIG. 9. Cumulative counts of impact parameters below the abscissa value for the population of Galactic accreting NS binaries eclipsed by a companion (green, in units of donor Roche lobe radius) or the Sun (orange, in Solar radii). Line styles indicate cuts on the donor mass.

by re-sampling the simulated population with replacement. Each Galactic component (e.g., the Thin Disk) is treated separately. The number of accreting NS binaries in each Galactic component population is found by multiplying the number of simulated binaries by the ratio of the Galactic component mass to the total mass required to generate the simulated accreting NS population. Every re-sampled binary is assigned a position based on its Galactic component distribution following [67] and a random inclination i that is uniform in $\cos i$.

The statistics from 500 Milky Way populations are summarized in Table III. To check the validity of our Milky Way population model, we compare to previous population synthesis studies. For our Thin Disk population, we first consider [73], which finds a total population of 2.2×10^6 NS-white dwarf binaries from a Thin Disk population with total mass $\sim 6 \times 10^{10} M_\odot$ formed at an exponentially decreasing star formation rate. We find a total population 5.9×10^6 NS-white dwarf binaries, without constraints on the donor mass or Roche lobe filling factor. Our yield is a factor of ~ 4 greater than [73] if we take into account our lower Thin Disk mass of $4.32 \times 10^{10} M_\odot$. For the Bulge population, we compare to [74], which simulated the population of low mass X-ray binaries (LMXBs) with NS accretors in the Bulge and predict a population of $\sim 2.1 \times 10^3$ NS LMXBs for a total Bulge mass of $1 \times 10^{10} M_\odot$. Our model roughly agrees with [74], though we predict a twice greater yield of NS LMXBs once we account for our relatively lower Bulge mass of $8.9 \times 10^9 M_\odot$. Direct comparisons between population synthesis studies which use different codes is difficult, thus rate differences within an order of magnitude are commonly accepted [75]. Scaling our populations down to match the numbers reported by

TABLE III. Accreting NS population statistics for the Galaxy. Here N_{MW} denotes the total number of accreting NSs expected in the galaxy with donors $> 0.05 M_\odot$, $N_{\text{Donor,ecl}}$ is the number of those that are eclipsed by their companions, and $N_{\odot,\text{ecl}}$ is the number of those expected to be eclipsed by the Sun.

Component	N_{MW}	$N_{\text{Donor,ecl}}$	$N_{\odot,\text{ecl}}$
Thin Disk	109,000	$36,000 \pm 160$	1500 ± 40
Thick Disk	1700	450 ± 20	20 ± 5
Bulge	3400	920 ± 30	30 ± 5

[73] and [74], does not change our general conclusions.

For each accreting NS we consider eclipses both by the donor companion and by the Sun. The impact parameter for the eclipse is

$$\frac{b}{R} = \frac{a}{R} \sin\left(\frac{\pi}{2} - i\right), \quad (22)$$

where for donor eclipses a is the binary semimajor axis, R is the donor Roche lobe radius, and i is the binary inclination; for Solar eclipses a is an astronomical unit, R is R_\odot and $\pi/2 - i$ is the ecliptic latitude.

Figure 9 shows the cumulative counts of impact parameters smaller than a given value for the populations of accreting NSs eclipsed by their donors (green) and by the Sun (orange) for a single Milky Way population. The different line styles show the fractions of the population which satisfy donor mass cuts of $M > 2.0 M_\odot$ and $M > 1.5 M_\odot$. As expected from Fig. 1, we find nearly two orders of magnitude fewer Solar eclipses than donor eclipses for our accreting NS population. We find a slight excess in the fraction of Solar eclipses when compared with the probability in Fig. 1 because NS accretors are highly concentrated in the Galactic plane, which intersects with the ecliptic plane.

V. DETECTABILITY

We consider in turn all three effects caused by an eclipse: magnification $\Delta h/h \equiv 1 - h'/h$, deflection in the apparent sky location due to lensing $\Delta\theta$, and the variation in the Shapiro time delay $\Delta t_s \equiv \Delta t(b) - \Delta t(R_\odot)$, as described in Eq. (4), Eq. (2), and Eq. (16), respectively. As shown in Section III, the characteristic magnitude of these effects for sources eclipsed by the Sun is

$$\frac{\Delta h}{h} \sim 0.01; \quad (23)$$

$$\Delta\theta \sim 1''; \quad (24)$$

$$\Delta t_s \sim 0.01 \text{ ms}. \quad (25)$$

As discussed in Section IV, in the case of a NS emitting GWs that is eclipsed by a binary companion, both the amplification and deflection are negligible, but the Shapiro time delay has a comparable magnitude as long as the mass of the companion star is comparable to that of the Sun.

Since the eclipse occupies only a small fraction of the overall observation, the measurement uncertainties from comparing the amplitude, location, and timing of the signal during the eclipse against the non-eclipse values are dominated by the uncertainties during the eclipse. Let ρ be the total signal-to-noise ratio (SNR) over the full observation, and ρ_{ec} the SNR during the eclipse. We assume that the SNR is proportional to the square root of the duration of the observation [76]. The scaling is weaker for initial detectability with a semi-coherent search [77], but we can assume that the source has already been detected, since that requires a much lower SNR than is necessary for measuring the eclipse properties, and a fully coherent analysis is used for parameter estimation. For example, for eclipses by the Sun, $\rho_{\text{ec}} \approx \rho(R_{\odot}/(\pi \text{ au}))^{1/2} \approx \rho(12 \text{ hr/yr})^{1/2} \approx 0.04\rho$. The SNR required for measuring the variation of the different effects over the course of an eclipse can be estimated by dividing the observation into shorter segments. For example, one-hour observations would have individual SNRs of $\sim \rho(1 \text{ hr/yr})^{1/2} \approx 0.01\rho$.

The accuracies of measuring the GW signal amplitude, sky location, and timing during the eclipse are (e.g., [78–80])

$$\frac{\delta h}{h} \sim \frac{1}{\rho_{\text{ec}}}; \quad (26)$$

$$\delta\theta \sim \frac{1}{\rho_{\text{ec}}} \frac{c\tau_{\text{GW}}}{v_{\oplus}\tau_{\text{ec}}} \simeq \frac{600''}{\rho_{\text{ec}}} \left(\frac{1000 \text{ Hz}}{f_{\text{GW}}} \right) \left(\frac{1 \text{ hr}}{\tau_{\text{ec}}} \right); \quad (27)$$

$$\delta t \sim \frac{\tau_{\text{GW}}}{\rho_{\text{ec}}} = \frac{1 \text{ ms}}{\rho_{\text{ec}}} \left(\frac{1000 \text{ Hz}}{f_{\text{GW}}} \right), \quad (28)$$

where $\tau_{\text{GW}} = 1/f_{\text{GW}}$ is the GW period, τ_{ec} is the duration of the observation, and $v_{\oplus} = 2\pi \text{ au yr}^{-1}$ is the orbital speed of the Earth. This allows us to compute the detectability of these quantities:

$$\frac{\Delta h}{\delta h} \sim 0.01\rho_{\text{ec}}; \quad (29)$$

$$\frac{\Delta\theta}{\delta\theta} \sim 0.002\rho_{\text{ec}} \left(\frac{f_{\text{GW}}}{1000 \text{ Hz}} \right) \left(\frac{\tau_{\text{ec}}}{1 \text{ hr}} \right); \quad (30)$$

$$\frac{\Delta t}{\delta t} \sim 0.01\rho_{\text{ec}} \left(\frac{f_{\text{GW}}}{1000 \text{ Hz}} \right). \quad (31)$$

As can be seen, for very high frequency sources with $f_{\text{GW}} \sim 10^3 \text{ Hz}$ and a time of observation of $\sim 1 \text{ hr}$ the detectability of the three effects are comparable in this order-of-magnitude analysis.

In order to make a useful measurement, a quantity such as $\Delta t/\delta t$ should at the least exceed 1. This corresponds to the requirement $\rho_{\text{ec}} > 100$ for a signal with a GW frequency of $\sim 1000 \text{ Hz}$. For eclipses by the Sun, this means that the full SNR must be $\rho > 2500$; for eclipses by the AMXP’s companion lasting 10% of the orbit, the requirement is a more modest $\rho > 300$. The SNR is expected to improve by a factor of $\sim 30 - 50$ at high frequencies between the Advanced LIGO observing run 2 sensitivity – the latest data for which continuous-wave upper limits

are available [28] – and next-generation detectors such as the Einstein Telescope [81] and the Cosmic Explorer [82]. Moreover, since semi-coherent searches with segments of length T_{seg} between half an hour and of order of one week were typically used in the past [28], the optimal coherent SNR would naturally be a factor of $(\text{yr}/T_{\text{seg}})^{1/4} \approx 3$ to 10 times greater. Thus, if there are favourably located sources at high frequencies just below the latest upper limits (corresponding to $\rho \gtrsim 10$, which would be translated to $\rho \gtrsim 1000$ with an optimal coherent analysis of next-generation data), it should be possible to observe eclipse signatures with next-generation detectors.

VI. CONCLUSIONS

We demonstrated how the observation of an eclipsing GW source provides unique information on the mass distribution of the eclipsing object, and showed that high frequency ($> 100 \text{ Hz}$) CWs are best suited for this purpose. For the case of a source eclipsed by the Sun, a GW signal would experience an apparent change in source position of a few arcseconds, a change in strain amplitude by up to $\sim 4\%$ and a Shapiro time delay of up to $\sim 0.03 \text{ ms}$. An even more likely possibility is that a source of GWs is eclipsed by a binary companion, in which case the only signature of the eclipse for an observer on Earth would be a variable time delay of a magnitude similar to that produced by the Sun.

The potential to observe lensing of CW sources depends upon the currently unknown amplitude of their GW emission. No CW sources have yet been detected. The effects of eclipses on the signal are small. Moreover, the SNR accumulated during the eclipse is a factor of ~ 3 to ~ 25 smaller than the total SNR. Therefore, eclipse lensing may be safely neglected for observations with current-generation detectors. However, if CW sources are just at the limit of the sensitivity of early current-generation detectors [83], eclipses could potentially be observed by next-generation detectors.

To obtain interesting constraints on the mass distribution of the eclipsing object will require SNRs of order of 10^3 . Such large SNRs may motivate the development of specialised detectors. Since a much larger SNR is required to measure the stellar interior than to detect a signal, we will know ahead of time the frequency of interest. This makes eclipsing CW sources an attractive target for tuneable narrow-band detectors. These can achieve enhanced sensitivity in a small range of frequencies compared to wide-band detectors. Tuneable detectors have been suggested for observations of binary neutron star coalescences, where they can track the inspiral and observe the post-merger signal [84–86], or to increase detection prospects for supernovae [87]. In comparison, eclipsing CW sources are a far simpler target, since detectors only need to focus on a single known frequency. Additionally, the timing of eclipses by the Sun can be predicted years in advance, so tuning does not need to be done dynam-

ically, but can follow a well-planned schedule. Observations from multiple eclipsing sources could be combined to give a more detailed map of the Sun's interior.

While eclipsing CWs provide a new probe of stellar interiors, we have not addressed the measurement precision necessary to provide meaningful constraints on stellar structure. For the Sun, helioseismology and neutrino detections already provide stringent constraints (cf. [88]). In this context, unless extremely bright high frequency sources of CWs are detected, even next-generation detectors might not be sufficient to improve upon the known constraints on the structure of the Sun. For the case when the eclipsing star is a binary companion to a GW source, neutrinos are undetectable, and asteroseismic measurements cannot be performed to the same precision as for the Sun. In this case, the measurement of eclipses of GW sources could provide a unique view into their stellar interiors. Despite its complexity, the detection of eclipses would provide an unbiased measurement of the mass distribution of a star, independent of uncertainties such as the composition or nuclear reaction rates.

Appendix A: Wave optics calculations

1. The Kirchhoff integral

Following the work of [4, 58], if the amplitude Ψ of a wave is known at a surface S surrounding the observer and inside which the wave propagates freely, its amplitude at the observer can be computed using the Kirchhoff integral,

$$\Psi_o = \frac{1}{4\pi} \int_S \left([\nabla \Psi] \frac{e^{ikr}}{r} - \Psi \nabla \left[\frac{e^{ikr}}{r} \right] \right) \cdot d\vec{A}, \quad (\text{A1})$$

where $k \equiv 2\pi/\lambda$ is the wavenumber and r is the distance between the observer and a point at the surface S . For

FIG. 10. Variables used for the computation of the Kirchhoff integral, in order to compute the effect of the Sun on GWs without the use of geometric optics. r is the distance between the observer and a point in the plane of the lens, while r' is the distance between the source and the same point. The distance l corresponds to the separation between the observer and the optical axis, which is the line that joins the source and the lens. Note that the lines of length r and r' are not necessarily coplanar, and are not meant to represent an actual trajectory (within the geometric optics approximation) from the source to the observer.

the particular case under consideration, the surface of integration can be taken to be the plane of the lens (see Fig. 10). The effect of the lens can be accounted for as a phase shift due to the time delay for a given impact parameter b ,

$$\Psi(b) = \frac{A_0}{r'} e^{i(kr' - \omega \Delta t(b))}, \quad (\text{A2})$$

where $\omega = 2\pi f_{\text{GW}}$ is the angular frequency of the wave, r' is the distance between the source and a point in the plane of the lens, and A_0 is a constant that sets the intensity of the wave. To compute the Kirchhoff integral we only consider the case of sources eclipsed by the sun and observed from Earth, in which case b' can be approximated as b (see Fig. 4). Here we ignore the phase shift ωt for the time evolution of the wave, as this factors out in the calculation of time delays and amplitude changes. Assuming $k \ll d_l^{-1}$ and $k \ll d_{ls}^{-1}$, combining Eq. (A1)

and Eq. (A2) results in

$$\Psi_o(l) = -\frac{ikA_0}{4\pi} \int_0^\infty \int_0^{2\pi} e^{i(kr+kr'-\omega\Delta t(b))} \times \frac{1}{rr'} \left(\frac{d_l}{r} + \frac{d_{ls}}{r'} \right) b d\varphi db, \quad (\text{A3})$$

where

$$r = \sqrt{d_l^2 + (l - b \cos \varphi)^2 + b^2 \sin^2 \varphi}, \quad (\text{A4})$$

$$r' = \sqrt{d_{ls}^2 + b^2}, \quad (\text{A5})$$

l is the distance of the observer from the optical axis while φ is an angle in the optical plane (see Fig. 10). Given $\Psi_o(l)$, the amplification of a GW observed at Earth is given by the ratio of $\Psi_o(l)$ to the expected amplitude in the absence of a lens,

$$\frac{h'(b)}{h} = \frac{|\Psi_o|(d_l + d_{ls})}{A_0}, \quad (\text{A6})$$

while the time delay can be computed by comparing the phase of the wave at different values of l ,

$$\omega|\Delta t_s| = \arccos \left[\frac{\Psi_o(b) \cdot \Psi_o(R_\odot)}{|\Psi_o(b)| |\Psi_o(R_\odot)|} \right], \quad (\text{A7})$$

where $\Psi_o(b) \cdot \Psi_o(R_\odot)$ denotes the complex dot product of $\Psi_o(b)$ and $\Psi_o(R_\odot)$.

The computation of Eq. (A4) can be simplified in the limit $l \ll d_l$, in which case

$$r = r_0 \left[1 + \frac{bl \cos \varphi}{r_0^2} - \mathcal{O} \left(\frac{b^2 l^2}{r_0^4} \right) \right], \quad (\text{A8})$$

where $r_0 = \sqrt{d_l^2 + b^2 + l^2}$. For the terms outside the exponential factor in Eq. (A3) one can simply approximate $r \simeq r_0$, but the term of order $\mathcal{O}(bl/r_0^2)$ in Equation (A8) needs to be included in the exponential to prevent errors in the phase larger than those induced by the lens. Under these approximations one has that

$$\Psi_o(l) = -\frac{ikA_0}{4\pi} \int_0^\infty \int_0^{2\pi} e^{i(kr_0+kr'+kbl \cos \varphi/r_0-\omega\Delta t(b))} \times \frac{1}{r_0 r'} \left(\frac{d_l}{r_0} + \frac{d_{ls}}{r'} \right) b d\varphi db, \quad (\text{A9})$$

and the integral over ϕ can be computed analytically resulting in

$$\Psi_o(l) = -\frac{ikA_0}{2} \int_0^\infty e^{i(kr_0+kr'-\omega\Delta t(b))} \times \frac{J_0(kbl/r_0)}{r_0 r'} \left(\frac{d_l}{r_0} + \frac{d_{ls}}{r'} \right) b db, \quad (\text{A10})$$

where J_0 is the Bessel function of the first kind and order zero.

Previous work on the impact of the Sun on GWs [4, 58] dealt with the change in amplitude of the wave near the caustics of the Solar lens (regions where multiple images

are formed). In this case the integral in Eq. (A10) is dominated by points around the value of b for which geometrical optics predicts rays converge at a distance d_l from the optical plane. This allows an analytical approximation of the result using the stationary phase approximation [89] and leads to the conclusion of [58] that no significant amplification occurs for frequencies $f_{\text{GW}} < 10^4$ Hz. The situation is different for an observer at Earth as the Earth is not located at a caustic of the Sun, requiring the calculation of the Kirchhoff integral in the entire lens plane; from our Solar model we predict caustics occur at a distance of $\gtrsim 20$ au from the Sun.

2. Numerical integration of the Kirchhoff integral

Numerically computing the integral in Eq. (A10) is difficult, as both the exponential term and the Bessel function change sign leading to a rapidly oscillating integrand. For $b \gg d_0$ we have that $r_0 \sim b$, such that the argument of the Bessel function becomes constant and only the rapid oscillation of the exponential factor remains problematic. To remedy this, we make the following change of variables:

$$y = r_0 + r' - d_{ls} - \sqrt{d_l^2 + l^2}, \quad (\text{A11})$$

$$dy = \left(\frac{1}{r_0} + \frac{1}{r'} \right) b db, \quad (\text{A12})$$

which, except for the time delay produced by the lens, leaves the argument of the complex exponential in Eq. (A10) as the integration variable. Ignoring constant phase shifts the wave amplitude is then

$$\Psi_o(l) = -\frac{kA_0 e^{ik\sqrt{d_l^2+l^2}}}{2} \int_0^\infty e^{i(ky-\omega\Delta t(b))} \times \frac{J_0(kbl/r_0)}{r_0 + r'} \left(\frac{d_l}{r_0} + \frac{d_{ls}}{r'} \right) dy. \quad (\text{A13})$$

We can then perform the integrand over each individual cycle produced by the term ky in the complex exponential, defining for an integer value j the quantity

$$A_j = -\frac{kA_0}{2} \int_{2\pi j/k}^{2\pi(j+1)/k} e^{i(ky-\omega\Delta t(b))} \times \frac{J_0(kbl/r_0)}{r_0 + r'} \left(\frac{d_l}{r_0} + \frac{d_{ls}}{r'} \right) dy, \quad (\text{A14})$$

such that

$$\Psi_o(l) = e^{ik\sqrt{d_l^2+l^2}} \sum_{j=0}^\infty A_j. \quad (\text{A15})$$

If there exists an N such that the value of A_j changes slowly with j for $j > N$, then it is useful to separate the sum to include all terms up to N , and express the rest as an integral,

$$\sum_{j=0}^\infty A_j = \sum_{j=0}^N A_j + \int_{N+1}^\infty A(x) dx \quad (\text{A16})$$

where $A(x)$ is a function that is equal to A_j with $j = \text{floor}(x)$ being the nearest integer to x that is smaller than x . Switching variables to $z = \ln x$ in the integral results in

$$\sum_{j=0}^{\infty} A_j = \sum_{j=0}^N A_j + \int_{\ln(N+1)}^{\infty} \frac{A(e^z)}{e^z} dz. \quad (\text{A17})$$

Since A_j varies slowly for $j > N$, the integral can be estimated by adding over logarithmic intervals Δz ,

$$\sum_{j=0}^{\infty} A_j \simeq \sum_{j=0}^N A_j + \sum_{m=0}^{\infty} \frac{A(e^{\ln(N+1)+m\Delta z})}{e^{\ln(N+1)+m\Delta z}} \Delta z. \quad (\text{A18})$$

This allows the calculation of the integral up to a large number of cycles, without individually computing the contribution of each one. Using this, we numerically compute the real and imaginary part of $\Psi_0(l)$. In addition, when evaluating cosines or sines in Eq. (A14),

rather than computing, for example, $\cos(ky - \omega\Delta t)$ we compute instead $\cos[k(y - 2\pi j/k) - \omega\Delta t]$. This prevents the evaluation of trigonometric functions with large arguments and reduces numerical errors.

Figure 11 shows an example of this integration, showing only the imaginary part of Ψ_o as the number of cycles n included in the calculation of the integral is increased. In this particular example the integral is directly computed up to $N = 10^6$, and then estimated up to 10^{15} cycles using 10^6 equally spaced logarithmic intervals. As it can be seen, the integral converges after 10^{10} cycles. Directly computing the integral up to that point is extremely expensive, which is the reason why we require the approximation discussed in this Appendix. Evaluating Eq. (A14) still requires a choice for d_{ls} and d_l . The calculations shown in Section III C were done using a distance between the lens and the source of $d_{ls} = 1$ pc, but we have verified that the resulting amplification and time delays are equivalent if the integrations are done using $d_{ls} = 0.1$ pc.

FIG. 11. Computation of the imaginary part of $\sum A_j$ for $l = 0.05R_\odot$, considering a 100 Hz source located at 1 parsec and observed at 1 au from the Sun. The ordinate-axis is normalized to the expected intensity of the wave in the absence of a lens. The abscissa-axis represents the number of cycles added (see Appendix A).
